

Chapter 2

Chemistry

In the beginning, it started with chemistry!

Atoms make molecules

Molecules combine to make macromolecules

Macromolecules organize into organelles

Organelles combine to form cells

Cells combine to make tissue

Tissue combine to make organs

Organs combine to make systems

Eleven different systems combine to make you!

Who first suggested matter is made up of atoms ?

Leucippus

Democritus

Leucippus is traditionally credited as the **founder of atomism**, which he developed with his student Democritus. Leucippus divided the world into two entities: atoms are indivisible particles that make up all things, and the void, the nothingness that exists between the atoms.

Democritus was a Greek pre-Socratic philosopher primarily remembered today for his formulation of an atomic theory of the universe. He advanced Leucippus idea. Known as the “Laughing Philosopher” because he believed happiness was the key to a good life (and probably because he found the ignorance of others amusing (c. 460–370 BCE),

Democritus Quotes:

- Nothing exists except atoms and empty space; everything else is opinion.
- > Happiness resides not in possessions, and not in gold, happiness dwells in the soul.
- > Throw moderation to the winds, and the greatest pleasures bring the greatest pains.

Largely ignored in ancient Athens, Democritus is said to have been disliked so much by Plato that the latter wished all his books burned. He was nevertheless well known to his fellow northern-born philosopher Aristotle. Many consider Democritus to be the "father of modern science". None of his writings have survived; only fragments are known from his vast body of work. (Wiki)

Aristotle: Later, **Aristotle** (c. 384–c. 322 B.C.) popularized the idea that all matter was made of earth, air, water, and fire in varying proportions. According to this notion, one should be able to make gold from other materials by adjusting the ratios of the four elements therein.

Aristotle's Four Elements

Aristotle's ideas influenced alchemy and protochemistry for **2,000 years**.

Physicist in the early 1800s and into the early 1900s investigated the structure of matter and determined that matter is made up of atoms.

Today we know atoms are constructed of three atomic particles: **protons, neutrons, and electrons**.

The ability of atoms to “link together” (form a chemical bond) is a function of the **electrons being shared or donated**.

The Modern Atomic Structure Timeline

John Dalton, English scientist, **developed the modern atomic theory in 1803** /// He demonstrated air is constructed out of Atoms and oxygen is eight times heavier than hydrogen.

The main points of Dalton's atomic theory:

- 1) Elements are made of extremely small particles called atoms.
- 2) Atoms of a given element are identical in size, mass and other properties
- 3) Atoms cannot be subdivided, created or destroyed. (This he got wrong because atoms can be subdivided into protons, neutrons, and electrons.)
- 4) Atoms of different elements combine in simple whole-number ratios to form **chemical compounds**.
- 5) In chemical reactions, atoms are combined, separated, or rearranged.

In the late 1700's Scientists in France and England started to study air.

They discovered air was made up of different types of air.

They called these gasses "special airs".

The special airs they discovered were oxygen, hydrogen, and carbon dioxide.

The Discovery of the Periodic Table

“The Most Important Document in the World”

	I	ПЕРИОДИЧЕСКАЯ СИСТЕМА ЭЛЕМЕНТОВ					VII	VIII		
1		II	III	IV	V	VI				
2	Li	Be

	Ag	Cd	In	Sn	Sb					
6					Ta	W	Re	Os	Ir	Pt
	Au		Tl	Pb	Bi					
7										
		Pr				Gd	Tb		Ho	

In 1869 Mendeleev used the mass and physical characteristics of known atoms (63 at the time) to construct a table consisting of **rolls (periods) and columns (groups)**.

His genius moment occurred when he realized that the blank spaces in his table represented yet to be discovered atoms! In the following decades, chemist worked to discovered the “missing atoms”.

Mendeleev's Periodic Table

Dmitri Mendeleev

1869

Figure 2.5 Dmitri Mendeleev's 1872 periodic table. The spaces marked with blank lines represent elements that Mendeleev deduced existed but were unknown at the time, so he left places for them in the table. The symbols at the top of the columns (e.g., R²O and RH⁴) are molecular formulas written in the style of the 19th century.

See Power Point - "Mendeleev: The Father of the Periodic Table"

Symbol

A one- or two-letter abbreviation derived from the element's English or Latin name.

Name

Element's common name.

Mass Number

The sum of the numbers of protons and neutrons in a specific isotope.

Atomic Number

Equal to the number of protons in the nucleus, as well as the number of electrons in the electron cloud.

Atomic Mass

Weighted average of the masses of all the element's isotopes. Rounding the atomic mass to the nearest whole number yields the mass number of the most common isotope.

 - Electrons (e^-)
-] Nucleus

(a) Electron cloud model

Valence electrons

(b) Electron shell model

atomic number

element symbol

element name

atomic weight

One proton

One electron

A few hydrogens in the element (group of similar atoms) gained a neutron. This is why hydrogen has a “little bit of extra weight”

75 proton

75 electron

111 neutron

If an atom has extra neutrons then it is called an isotope. This will make some atoms unstable and they are then referred to as radioactive isotopes.

→ Atomic number

→ Atomic weight

What is an isotopes – same atoms that differ from one another only in the number of neutrons and therefore, in atomic mass

Atomic weight of an element accounts for the fact that an element is a mixture of atoms (atoms with equal protons and neutrons and those atoms that are isotopes)

FEATURE		PERIODS	GROUPS
	Direction	Horizontal rows	Vertical columns
	Total number	7	18
	Electron shells	Same number	Increase down the group
	Valence electrons	Different	Same
	Chemical properties	Gradually change	Very similar

CHARACTERISTICS OF PERIODS

1

Atomic number increases from left to right.

2

Atomic size **decreases** across a period because nuclear charge increases.

3

Metallic character **decreases** across a period.

4

Non-metallic character increases across a period.

5

Electronegativity **increases** from left to right.

GROUPS IN THE PERIODIC TABLE

DEFINITION OF GROUPS

@Chemistry_K2023

- Groups are the vertical columns in the periodic table.
- There are 18 groups in the modern periodic table.
- Elements in the same group have similar chemical properties because they have the same number of valence electrons.

Periodic Table of Elements is the Alphabet of the Universe

Periodic Table - arrange atoms by the number of protons in nucleus and the atom's physical properties

Elements represented by one or two letter symbols

Atomic number tell us the number of protons in the atom

Atomic mass tell us the number of protons and neutrons in the atom

The rows are called **periods** // as you go down the table each row indicates the next shell (orbit)

All atoms in the same column (called a **group**) will have the same number of electrons (**valence electrons**) // valence electrons determine bonding characteristics of the atom

24 elements have biological role /// **6 elements = 98.5% of body weight**

–oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus

–additional trace elements occur in smaller amounts

Atomic Structure

(Five Test Questions!)

The nucleus = at the center of the atom // location for protons and neutrons

Protons = single positive charge, mass = 1 amu (atomic mass unit) or Dalton

Neutrons = no charge, mass = 1 amu (or Dalton)

Number of protons = number of neutrons (some atoms may have different number of neutrons – call isotopes)

Atomic number = protons

Atomic mass (weight) = number of protons and neutrons

Atom's charge is neutral because number of **electrons are equal to the number of protons**

Electrons = negative charged particles / little mass (.0005 Daltons) / travel at speed of light around nucleus in discrete patterns called **orbits or electron shells** // outer most electrons called **valence electrons**

Periodic Table

7																		

Periods are the rows. Each period adds another “orbit” circling the nucleus. Electrons fill the orbital shells using the “octet rule”.

Groups are the columns. Atoms in a column will all have the same number of electrons in their outer shell.

Important Knowledge About Atomic Structure!

Number of protons determine the chemical properties of the atom // the characteristic of the atom (e.g. carbon = 6 protons and gold = 79 protons)

Valence electrons // electrons in outer most orbit determine how individual atoms bind to each other // follows the octet rule

Na 2:8:1

Sodium atomic number is 11. It has 11 protons, 11 electrons, and 11 neutrons.
What is the atomic weight of sodium?

Timeline of Atomic Models

Plum Pudding Model (1904)

• J.J. Thompson

Nuclear Model (1911)

• Ernest Rutherford

Bohr Model (1913)

• Niels Bohr

Quantum Mechanical Model (1920s)

• Erwin Schrödinger

What model of the atom is most useful to explain simple chemical bonding?
Answer: the Bohr Model

How Our Understanding of the Atomic Structure Changed Over Time

JJ Thomson discovers electrons 1897 and advanced a model of the atom called the **plum pudding theory**. The negative electrons were “balanced” by a positive proton.

Heating the cathode causes negative particles (**electrons**) to be emitted from the cathode and projected towards the positive anode. (vacuum tube)

How Our Understanding of the Atomic Structure Changed Over Time

Ernest Rutherford in 1911 disproved the plum pudding model and demonstrated protons were in the center of the atom and electrons encircled the protons as a “cloud”. The **electron cloud model**.

How Our Understanding of the Atomic Structure Changed Over Time

Neils Bohr, Danish physicist, proposed a **planetary model of atomic**, a structure similar to planets orbiting the sun (1865 – 1962 He was awarded the Noble Prize 1922 for his work.

How Our Understanding of the Atomic Structure Changed Over Time

Neils Bohr, Key contribution – electrons travel not in a cloud but in discrete orbits.

If electrons are “excited” (given extra energy) the electrons may move into another orbit. Bohr showed how atoms could combine to form molecules.

He invented chemistry. How atoms join to form molecules. Chemistry is the study of matter.

Atoms consist of three “elemental atomic particles” (Protons – Neutrons – Electrons). Note – neutrons were not discovered until the 1930s.

To understand basic chemistry, you only need *to understand the relationship between protons, neutrons, and electrons*

In the 1960s we started to understand that the atomic particles are constructed of even smaller “subatomic particles”, however. (*If curious see The Standard Model – articles and videos on Web site*)

James Chadwick

1932

- Discovered neutrons
- Neutral particle with mass close to proton

This discovery allowed scientist to realize that they could project a neutral particle (the neutron) into an atom's positively charged nucleus to break apart the nucleus. This would then cause a chain reaction. This led to the development of the nuclear bomb.

DISCOVERY OF NEUTRONS

Chadwick smashed alpha particles into beryllium, a rare metallic element, and allowed the radiation that was released to hit another target: paraffin wax. The experiment results showed a collision with beryllium atoms would release massive neutral particles, which Chadwick named neutrons.

The Evolution of the Atomic Model in the 20th Century

Dalton – atoms are “indivisible” / like billiard balls

J.J. Thomson – plum pudding model

Rutherford – electron cloud model

Bohr – electron orbital model (created chemistry!)

Heisenberg & Schrodinger – electron wave model

(Not a lecture topic)

Number of Orbitals and Their Capacity

d sublevel

There are **5 *d* orbitals** in a given energy level.

There can be a maximum of **10 electrons** in a *d* sublevel.

p sublevel

There are **3 *p* orbitals** in a given energy level.

There can be a maximum of **6 electrons** in a *p* sublevel.

s sublevel

There is **one *s* orbital** in a given energy level.

There can be a maximum of **2 electrons** in an *s* sublevel.

Periodic Table showing last orbital filled for each element

Chemical Bonds

Chemical bonds – forces that hold two or more atoms together, or forces that attract one molecule to another molecule

Types of Chemical Bonds

- Covalent bonds
- Hydrogen bonds
- Ionic bonds
- Van der Waals force (not required)

TABLE 2.3

Types of Chemical Bonds

Bond Type	Definition and Remarks
Ionic bond	Relatively weak attraction between an anion and a cation. Easily disrupted in water, as when salt dissolves.
Covalent bond	Sharing of one or more pairs of electrons between nuclei.
Single covalent	Sharing of one electron pair.
Double covalent	Sharing of two electron pairs. Often occurs between carbon atoms, between carbon and oxygen, and between carbon and nitrogen.
Nonpolar covalent	Covalent bond in which electrons are equally attracted to both nuclei. May be single or double. Strongest type of chemical bond.
Polar covalent	Covalent bond in which electrons are more attracted to one nucleus than to the other, resulting in slightly positive and negative regions in one molecule. May be single or double.
Hydrogen bond	Weak attraction between polarized molecules or between polarized regions of the same molecule. Important in the three-dimensional folding and coiling of large molecules. Easily disrupted by temperature and pH changes.
Van der Waals force	Weak, brief attraction due to random disturbances in the electron clouds of adjacent atoms. Weakest of all bonds.

The Octet Rule

The octet rule is a simple chemistry guideline stating that atoms "want" to have eight electrons in their outer shell (valence shell) to be stable, just like [noble gases](#).

To achieve this, atoms will gain, lose, or share electrons with other atoms, forming chemical bonds ([ionic](#) or [covalent](#)), so everyone ends up with a full "octet" of eight electrons for maximum stability.

The octet rule applies best to atoms in the first three periods. The rule helps us understand the difference between covalent and ionic bonds. As the atomic number increases then other rules apply.

Sodium atomic number 11. How many neutrons? How many electrons?
Sodium needs to lose an electron to meet octet rule. What happens to the atoms charge?

Chlorine atomic number is 17. How many neutrons? How many electrons?
Chlorine needs to add an electron to meet the octet rule? What happens to the charge?

The octet rule

Atoms can gain a full valence shell by either sharing electrons (covalent bonding) or by transferring electrons (ionic bonding).

Covalent bonding (CH_4)

Ionic bonding (NaCl)

Covalent Bonds

Formed by sharing “valence electrons”

Types of covalent bonds

- single** - sharing of single pair electrons
- double** - sharing of 2 pairs of electrons

Nonpolar covalent bond

shared electrons spend approximately equal time around each nucleus /// strongest of all bonds

Polar covalent bond

When shared electrons spend more time orbiting one nucleus than they do the other, they lend their negative charge to the area they spend most time

Molecular Formulas and Molecular Weight

Covalent Molecule = occurs when two or more atoms share electrons (chemical bond) // e.g. Oxygen or O₂

Compound = substance that contains atoms of two or more different elements // e.g. water or H₂O

The molecular weight of a compound = sum of atomic weights of all the atoms

Calculate: MW of glucose (C₆H₁₂O₆)

6 C atoms x 12 amu each = 72 amu

12 H atoms x 1 amu each = 12 amu

6 O atoms x 16 amu each = 96 amu

Molecular weight (MW) = 180 amu

Borh's Model of Elements

p⁺ represents protons, n⁰ represents neutrons

Single Covalent Bond

Pair of electrons are shared

Note: single line denotes two electrons are shared between two atoms.

Ionic Bonds

The attraction of a cation (positive charged atom) to an anion (negative charge atom)

Electrons are donated by one atom and received by a different atom

Relatively weak attraction -- easily disrupted in water (e.g. when table salt dissolves in water)

This is not a covalent bonds because electrons are not “shared” but donated!

What happens to the charge of each atom after electron moves?

Ions and Ionization

Ions – charged particles with unequal number of protons and electrons

Ionization - transfer of electrons from one atom to another

Key idea is to have atom with either “two or eight electrons” in the valence shell

First orbit = maximum two electrons

Second and third orbits = maximum eight electrons

① Transfer of an electron from a sodium atom to a chlorine atom

Anions and Cations

- **Anion** // atom that gained electrons (net negative charge)
- **Cation** // atom that lost an electron (net positive charge)
- Ions with opposite charges are attracted to each other

② The charged sodium ion (Na^+) and chloride ion (Cl^-) that result

(a) Sodium: 1 valence electron

Sodium atom has no charge because it has the same number of neutrons and protons.

Sodium ion has a positive charge because the sodium atom lost an electron.

Ion

(b) Chlorine: 7 valence electrons

(c) Ionic bond in sodium chloride (NaCl)

Note: octet rule

(d) Packing of ions in a crystal of sodium chloride

What is a hydration sphere? Significance?

1. What is the orientation of water molecule?
2. What is the difference between water soluble (hydrophilic) and non-water soluble (hydrophobic)?
3. How will water molecules interact with protein and fat? Why?

The behavior of hydrophilic molecules in water.

(a) Ionic compounds are hydrophilic.

What is the behavior of hydrophilic molecules in water?

(b) Polar covalent compounds are hydrophilic.

What is the behavior of hydrophobic molecules in water?

(c) Nonpolar covalent compounds are hydrophobic.

Hydrogen Bonds

Hydrogen bond = a weak attraction between a slightly positive hydrogen atom in one molecule and a slightly negative oxygen or nitrogen atom in another molecule.

Water molecules are weakly attracted to each other by hydrogen bonds
Relatively weak bonds

Very important to physiology structure and function

- Structure - Protein structure & DNA structure
- Function - Respiratory failure of premature infants

Note – Hydrogen bonds do not hold atoms together, so they don't form compound, however.

Hydrogen bonds opposite charge between two molecules or across from opposite charges in the same molecule. Therefore, hydrogen bonds....

- 1) Hold 3D shape of same molecule together (e.g. protein)
- 2) Hold different molecules together (e.g. water molecules)

Hydrogen Bonding in Water

What is a gel state?

What is water tension?

What happens when water freezes?

Why does ice float?

Why Does Water Expand When It Freezes

As water freezes the hydrogen bonds push the H_2O molecules farther apart from each other increasing the intermolecular space resulting in expansion.

Liquid water

Unstable and irregularly formed hydrogen bonds

On Freezing

molecules form
stable hexagonal
crystal lattice
structure

Ice

Stable hydrogen bonds

- DNA is made of two strands twisted in a spiral staircase-like structure called a double helix.
- Each strand consists of nucleotides bound together.
- Each nucleotide consists of a deoxyribose sugar bound to a phosphate group and one of 4 nitrogenous bases [adenine (A), thymine (T), guanine (G), cytosine (C)].
- The nitrogenous bases pair together through hydrogen bonding to form the “steps” of the double helix.
- Adenine pairs with thymine and guanine pairs with cytosine.

- A
- G
- T
- C
- U

Alpha helix

bonds)

Beta pleated sheet

What is an isomer?

Isomers – molecules with identical molecular formulae but different arrangement of their atoms

	Structural formulae	Condensed Structural formulae	Molecular formulae
Ethanol	$\begin{array}{c} \text{H} & \text{H} \\ & \\ \text{H}-\text{C}-\text{C}-\text{OH} \\ & \\ \text{H} & \text{H} \end{array}$	$\text{CH}_3\text{CH}_2\text{OH}$	$\text{C}_2\text{H}_6\text{O}$
Ethyl ether	$\begin{array}{c} \text{H} & & \text{H} \\ & & \\ \text{H}-\text{C}-\text{O}-\text{C}-\text{H} \\ & & \\ \text{H} & & \text{H} \end{array}$	CH_3OCH_3	$\text{C}_2\text{H}_6\text{O}$

Free Radicals

FR are chemical particles with an “unpaired electron in outer shell” // *FR need another electron to make atom stable.*

FR will “take” an electron from another molecule which then makes that molecule unstable. The second molecule then takes an electron off another molecule. This starts a chain reaction which could eventually kill the cell.

Produced by /// normal metabolic reactions in mitochondria, radiation, or toxic chemicals

FR damage tissue / may cause cell death!

- reactions that destroy cellular molecules
- may cause cancer, death of heart tissue and aging

Antioxidants - neutralize free radicals

- in our tissues we have the enzyme superoxide dismutase (SOD)
- in diet (Selenium, vitamin E, vitamin C, carotenoids)

Free Radicals

Fig. An Example of a Free Radical

Definition:

Free radicals are chemical species that contain **single unpaired electron** in an **outer orbit**.

- Unstable & highly reactive
- Autocatalytic Reaction
- Induce cell injury
- Has role in phagocytosis

Superoxide (O₂^{•-}):

A free radical formed by the addition of a single electron to a molecule of oxygen. It is a precursor to other ROS and is produced by various cellular processes, including the electron transport chain in mitochondria and by NADPH oxidases. 

Hydrogen Peroxide (H₂O₂):

A non-radical ROS that is formed from superoxide by the enzyme superoxide dismutase (SOD). It is relatively stable and can diffuse across cell membranes, potentially reaching different cellular compartments. 

Hydroxyl Radical (•OH):

The most reactive of the common ROS, it is formed from hydrogen peroxide in the presence of transition metal ions like iron. It can cause significant cellular damage by reacting with lipids, proteins, and DNA. 

Singlet Oxygen (1O₂):

An electronically excited form of oxygen that is highly reactive. It can be generated by various reactions, including those involving hydrogen peroxide and hypochlorous acid. 

Examples of Free Radicals

- ROS (Reactive Oxygen Species)
 - Superoxide Anion $\text{O}_2^{\cdot-}$
 - Hydrogen Peroxide H_2O_2
 - Hydroxyl Radical $\text{HO}^{\cdot}$
- NO (Nitric Oxide)
- ONOO^- (Peroxynitrite Anion)
- NO_2 , NO_3^-

Nitric oxide

How Do We Neutralize Free Radicals?

(a) Oxygen molecule (O_2)

Unpaired electron

(b) Superoxide free radical (O_2^-)

Superoxide dimutase

Catalase

Peroxidase

Hydrogen peroxide

How Free Radicals Are Generated ?

- By **Reduction-Oxidation Reactions** during normal metabolic processes
- Absorption of **Radiant Energy**
- During **Inflammation**
- During **Enzymatic Metabolism** of Exogenous Chemicals and Drugs
- **Transition Metals**
- NO generated by **endothelial cells, neurons, macrophages** etc. combines with superoxide and forms peroxynitrate (ONOO^-)

(NO = nitric oxide)

Nitric oxide

How Free Radicals Are Removed ?

- Antioxidants: Vitamin A, C, E and Glutathione
- Binding Transition Metals With Storage And Transport Proteins
- By Free Radical Scavenging System
 - Catalase : $2\text{H}_2\text{O}_2 \rightarrow \text{O}_2 + 2\text{H}_2\text{O}$
 - Superoxidase dismutases
 - Glutathione peroxidase :
 - $\text{H}_2\text{O}_2 + 2\text{GSH} \rightarrow \text{GSSG} + 2\text{H}_2\text{O}$
 - $2\text{OH} + 2\text{GSH} \rightarrow \text{GSSG} + 2\text{H}_2\text{O}$

ATOMS

**FREE
RADICALS**

Mitochondrial
Damage

+ Oxygen = Reperfusion Injury

Reperfusion produces free radicals. Danger following medical procedures.

Free radicals are also produced by inflammation / neutrophils
respiratory burst / oxygen is converted to free radicals by WBC

Neutrophils (WBC) Form Free Radicals to Kill Bacteria

NADPH may also be used to reduce free radicals to make them harmless.

Isotopes and Radioactivity

Isotopes – same element (because atom has same number of protons) but differ from one another only in the number of neutrons (different atomic mass)

Extra neutrons increase atomic weight

Isotopes of an element are chemically similar // have same valence electrons

An isotope has an imbalance between the number of protons and neutrons in the nucleus // atom will try to bring this back into balance by beta decay.

Isotopes and Radioactivity

Not all isotopes are radioactive; there are both stable and unstable (radioactive) isotopes, with stability depending on the balance of protons and neutrons in the nucleus, so atoms like Carbon-12 and Oxygen-16 are stable, while Carbon-14 is radioactive.

Only isotopes with excess internal energy or an imbalance of particles are unstable and undergo radioactive decay, releasing radiation until they become stable.

Iodine Radioisotope

Radioisotopes

- One of iodine's neutron is converted to a proton
- When this occurs a beta particle is ejected from the nucleus
- A beta particle is a high energy electron
- The atomic weight does not change but the number of protons change (increases by one and a new element is formed)
- Every element has at least one radioisotope

Radioactivity

- radioisotopes decay to stable isotopes by releasing radiation
- atom has an imbalance in number of protons to neutrons

Isotopes of Hydrogen

Hydrogen (^1H)
(1p⁺, 0n⁰, 1e⁻)

Deuterium (^2H)
(1p⁺, 1n⁰, 1e⁻)

Tritium (^3H)
(1p⁺, 2n⁰, 1e⁻)

The numbers and dial are painted with phosphate.

Tritium beta emissions cause
phosphorous to glow

(not a lecture topic)

Proton = two up quarks and one down quark

Neutron = one down quark and two up quarks

If you have too many neutrons then the atom will change a neutron into a proton by “flipping” one of the quarks and “ejecting” an electron. This transforms hydrogen (1 proton) into helium (two protons). If the “ejected electron” (called a beta particle) hits a phosphate atom, then it excites the phosphate’s electrons to jump to a higher energy level. When the electron drops down to its normal energy level, it emits a photon (light).

Radioactive tritium undergoes beta negative decay. A neutron is converted To a proton and an electron is ejected.

(not a lecture topic)

Beta Decay

Beta decay is radioactive decay that either releases an electron (beta minus) or positron (beta plus).

5	6	7
B	C	N
Boron	Carbon	Nitrogen
10.811	12.0107	14.0067

Beta decay (β^- VS β^+)

Beta minus decay (β^-), a neutron is converted to a proton, and the process creates an electron and an electron antineutrino

B plus decay (β^+), a proton is converted to a neutron, and the process creates a positron and an electron neutrino. β^+ decay is also known as positron emission.

(not a lecture topic)

Positron emission, beta plus decay, or β^+ decay is a subtype of radioactive decay called beta decay, in which a proton inside a radionuclide nucleus is converted into a neutron while releasing a positron and an electron neutrino (ν_e).

Sidharth

Mar 22, 2015

Positron emission or beta plus decay (β^+ decay) is a particular type of radioactive decay and a subtype of [beta decay](#), in which a proton inside a radionuclide nucleus is converted into a neutron while releasing a positron and an electron neutrino (ν_e).

[1] Positron emission is mediated by the weak force. The positron is a type of beta particle (β^+), the other beta particle being the electron (β^-) emitted from the β^- decay of a nucleus.

Okay coming to the point

[Isotopes](#) which undergo this decay and thereby emit positrons → carbon-11

- potassium-40,
- nitrogen-13,
- oxygen-15,
- aluminium-26,
- sodium-22,
- fluorine-18,
- iodine-121.

(not a lecture topic)

Electrolytes

Salts that ionize in water and form solutions capable of conducting an electric current.

Electrolyte importance

- chemical reactivity
- osmotic effects (influence water movement)
- electrical effects on nerve and muscle tissue

Electrolyte balance is one of the most important considerations in patient care.

Imbalances have ranging effects from muscle cramps, brittle bones, to coma, cardiac arrest, and death.

TABLE 2.2

Major Electrolytes and the Ions Released by their Dissociation

Electrolyte		Cation	Anion
Calcium chloride (CaCl_2)	→	Ca^{2+}	2Cl^-
Disodium phosphate (Na_2HPO_4)	→	2Na^+	HPO_4^{2-}
Magnesium chloride (MgCl_2)	→	Mg^{2+}	2Cl^-
Potassium chloride (KCl)	→	K^+	Cl^-
Sodium bicarbonate (NaHCO_3)	→	Na^+	HCO_3^-
Sodium chloride (NaCl)	→	Na^+	Cl^-

Minerals

Inorganic elements **extracted from soil** by plants and passed up the food chain to humans

Some important minerals: Ca, P, Cl, Mg, K, Na, I, Fe, Zn, Cu, and S

Constitute about 4% of body weight

Important part of the structure in teeth, & bones

Required as co-factor for some enzymes

The minerals are the electrolytes – required for nerve function, muscle function, and membrane potentials.

TABLE 2.1**Elements of the Human Body**

Name		Symbol	Percentage of Body Weight
Major Elements (Total 98.5%)			
Oxygen		O	65.0
Carbon		C	18.0
Hydrogen		H	10.0
Nitrogen		N	3.0
Calcium		Ca	1.5
Phosphorus		P	1.0
Lesser Elements (Total 0.8%)			
Sulfur		S	0.25
Potassium		K	0.20
Sodium		Na	0.15
Chlorine		Cl	0.15
Magnesium		Mg	0.05
Iron		Fe	0.006
Trace Elements (Total 0.7%)			
Chromium	Cr	Molybdenum	Mo
Cobalt	Co	Selenium	Se
Copper	Cu	Silicon	Si
Fluorine	F	Tin	Sn
Iodine	I	Vanadium	V
Manganese	Mn	Zinc	Zn

Van der Waals Forces

(not a learning objective)

Van der Waals Forces – weak, brief attractions between neutral atoms

Fluctuations in electron density in electron cloud of a molecule creates polarity for a moment, and can attract adjacent molecules in the region for a very short instant in time

Only 1% as strong as a covalent bond

When two surfaces or large molecules meet, the attraction between large numbers of atoms can create a very strong attraction

- important in protein folding
- important with protein binding with hormones
- association of lipid molecules with each other

More About Water

Polar covalent bonds and its **V-shaped molecule** gives water a set of properties that account for its ability to support life.

Water's unique features include.....

- solvency**
- cohesion**
- adhesion**
- chemical reactivity**
- thermal stability**

Solvency

Solvency - ability to dissolve other chemicals

Water is called the **Universal Solvent**

Hydrophilic – substances that dissolve in water //
These molecules must be polarized or charged (e.g. proteins)

Hydrophobic - substances that do not dissolve in water
// These molecules are non-polar or neutral (e.g. fat)

All biologic chemical reactions depend on the solvency of water

Water as a Solvent

Polar water molecules overpower the ionic bond in $\text{Na}^+ \text{Cl}^-$

- forming **hydration spheres** around each ion
- water molecules: negative pole faces Na^+ , positive pole faces Cl^-
- Water also interacts with surface charge on proteins // water is
- responsible for folding proteins into 3D shape!

Chemical Reactivity of Water

It is the ability of water to participate in chemical reactions

- water ionizes** into H^+ and OH^-
- water ionizes** other chemicals (acids and salts)
- water involved in **hydrolysis** and **dehydration synthesis** reactions

Thermal Stability of Water

Water helps stabilize the internal temperature of the body

Has high **heat capacity** – the amount of heat required to raise the temperature of 1 g of a substance by 1 degree C.

calorie (cal) – the amount of heat that raises the temperature of 1 g of water 1 degree C.

Hydrogen bonds inhibit temperature increases by inhibiting molecular motion (note: heat is actually a measurement of velocity!)

Water absorbs heat without changing temperature very much

Effective coolant // 1 ml of perspiration removes 500 calories

Three Types of Mixtures

Solution, Colloid and Suspension

Solution Colloid

Suspension

Water and Mixtures

Three Types of Mixtures

Mixtures – consists of substances physically blended, but not chemically combined

Our body fluids are complex mixtures of chemicals

Each substance in a mixture maintains its own chemical properties (no chemical bonding occurs)

Most mixtures in our bodies consist of chemicals dissolved or suspended in water

Water 50-75% of body weight // depends on age, sex, fat content, etc.

Solutions

Solution – consists of particles of matter called the **solute** mixed with a more abundant substance (usually water) called the **solvent**

Solute can be gas, solid or liquid

Solutions are defined by the following properties:

- solute particles under 1nm
- solute particles do not scatter light
- will pass through most membranes
- will not separate on standing

Solution

Particles extremely small and not visible; do not settle out; one component dissolves in the other component.

Colloids

Most common colloids in the body is a mixture of **protein** and water

May change from liquid to gel state within and between cells

Colloids defined by the following physical properties:

- particles range from 1 – 100 nm in size
- scatter light and are usually cloudy
- particles too large to pass through semipermeable membrane
- particles remain permanently mixed with the solvent when mixture stands

Colloid

**Two distinct components;
particles small and not visible; but do not settle out; hydrated.**

Suspensions and Emulsions

Suspension

Defined by the following physical properties

Particles exceed 100nm

Too large to penetrate selectively permeable membranes

Cloudy or opaque in appearance

Separates on standing

Emulsion // suspension of one liquid in another // e.g. fat in milk

Suspension

**Particles large and
usually visible; settle out.**

Copyright © The McGraw-Hill Companies, Inc. Permission required for reproduction or display.

TABLE 2.4

Types of Mixtures

	Solution	Colloid	Suspension
<i>Particle Size</i>	< 1 nm	1-100 nm	> 100 nm
<i>Appearance</i>	Clear	Often cloudy	Cloudy-opaque
<i>Will particles settle out?</i>	No	No	Yes
<i>Will particles pass through a selectively permeable membrane?</i>	Yes	No	No
<i>Examples</i>	Glucose in blood O ₂ in water Saline solutions Sugar in coffee	Proteins in blood Intracellular fluid Milk protein Gelatin	Blood cells Cornstarch in water Fats in blood Kaopectate

pH

pH is a scale that measures the number of “free” protons (H^+) in the water

The greater the hydrogen ion concentration, the lower the pH number

Strong acid = pH 0 // Strong base = pH 14 // water pH is 7

Measurement of molarity of H^+ [H^+] on a logarithmic scale

pH scale invented by Soren Sorensen in 1909 to measure acidity of beer

$$pH = -\log [H^+] \text{ thus } pH = -\log [10^{-3}] = 3$$

Acids, Bases, Salts

An **acid** is proton donor (releases H^+ ions in water)

A **base** is proton acceptor (accepts H^+ ions) // (NaOH is a base because it dissociated into a OH^- ions and the hydroxyl group and a free proton binds to the OH^-)

pH – a measure derived from the molarity of H^+

a pH of 7.0 is neutral pH // ($H^+ = OH^-$)

a pH of less than 7 is acidic solution // ($H^+ > OH^-$)

a pH of greater than 7 is basic solution // ($OH^- > H^+$)

What is the difference in water's pH if the proton is attached to a protein by a hydrogen bond or the proton is “free” in the water?

The behavior of acids and bases in water.

(a) Some water molecules dissociate to H^+ and OH^- . In pure water, the numbers of H^+ and OH^- are equal.

What happens if you add equal amount of HCl and KOH together?

Answer: You make water and a salt!

The behavior of acids and bases in water.

(a) Some water molecules dissociate to H^+ and OH^- . In pure water, the numbers of H^+ and OH^- are equal.

Add acid

(b) An acid (HCl) releases H^+ and so increases the H^+ concentration of the solution.

Add base

(c) A base ($NaHCO_3$) binds free H^+ and so decreases the H^+ concentration of the solution.

pH

One **number change** on the pH scale represents a 10 fold change in H^+ concentration

A solution with pH of 4.0 is 10 times as acidic as one with pH of 5.0

A buffer resist the change in pH // Our body use **buffers** to maintain pH homeostasis

Slight pH disturbances can disrupt physiological functions and alter drug actions

pH of blood ranges from 7.35 to 7.45

Deviations from this range cause tremors, paralysis or even death

pH Scale

Chemical Reaction

Chemical reaction – a process in which a covalent or ionic bond is formed or broken

Chemical equation – symbolizes the course of a chemical reaction

Reactants (on left) → products (on right)

Classes of chemical reactions

- decomposition reactions
- synthesis reactions
- exchange reactions

Carbon atoms forms the “backbone” for the macromolecules of life. Carbon's four valence electrons allow carbon to make macromolecules that form linear chains, branching chains, and ring structures.

Another way to show a hydrocarbon chain; the C atoms are at each point, and the H atoms are not shown.

Another way to show a hydrocarbon ring; the C atoms are at each corner, and the H atoms are not shown.

Decomposition Reactions

Large molecule breaks down into two or more smaller ones

Copyright © The McGraw-Hill Companies, Inc. Permission required for reproduction or display.

(a) Decomposition reaction

Synthesis Reactions

Two or more small molecules combine to form a larger one

Copyright © The McGraw-Hill Companies, Inc. Permission required for reproduction or display.

(b) Synthesis reaction

Exchange Reactions

Two molecules exchange atoms or group of atoms

Stomach acid (HCl) and sodium bicarbonate (NaHCO₃) from the pancreas combine to form NaCl and H₂CO₃.

(c) Exchange reaction

+

+

Reversible Reactions

Reversible means the equation can go in either direction

Symbolized with double-headed arrow

This is the most important reversible equations in human physiology

Memorize this equation: /// carbon dioxide plus water forms carbonic acid which dissociates into bicarbonate and a proton. (What is a proton?)

Bicarbonate is a weak base. // Carbonic acid is a weak acid

It plays a critical role in the respiratory system, urinary system, digestive system, and many other physiologic mechanisms

What determines the direction of the reaction? (see next slide)

Reversible Reactions

Law of mass action determines direction

Proceeds from the side of equation with greater quantity of reactants to the side with the lesser quantity

Required enzyme (biocatalyst) **carbonic anhydrase / inside RBC**

Equilibrium exists when the concentration of products to reactants is equal

What will happen to this proton?
Significance?

CO₂ is produced inside the mitochondria of our cells throughout body. High CO₂ and low bicarbonate concentrations push equation to the right.

CO₂ becomes carbonic acid
Carbonic anhydrase changes carbonic acid into bicarbonate.
Now the CO₂ is transported in the blood as bicarbonate.

When bicarbonate reaches the lung tissue, there is very little CO₂ but very high concentrations of bicarbonate. This now moves the equation to the left and CO₂ forms. Now lungs excrete CO₂

Reaction Rates

Basis for chemical reactions is **molecular motion** and **collisions** //

Reactions occur when molecules collide with enough force and the correct orientation

Reaction Rates affected by:

–**Concentration** // reaction rates increase when the reactants are more concentrated

–**Temperature** // reaction rates increase when the temperature rises

–**Catalysts** –substances that temporarily bond to reactants, hold them in favorable position to react with each other, and may change the shapes of reactants in ways that make them more likely to react.

- speed up reactions without permanent change to itself
- holds reactant molecules in correct orientation
- catalyst not permanently consumed or changed by the reaction
- enzymes are important biological catalysts**

What is an enzyme? What is a substrate?

What macromolecules make enzyme's structure?

Where is the information in a cell stored to make this macromolecule?

What maintains the shape of an enzyme?

How may you “damage” an enzyme?

Why is the enzyme called a functional protein and not a structural protein?

Multienzyme Systems

Linear

Example:
Glycolysis

Cyclic

Branched

Divergent

Convergent

Examples of metabolic pathways.

Metabolism

Metabolism = All the chemical reactions that occur within a cell

Catabolic // energy releasing (exergonic) decomposition reactions

- breaks covalent bonds
- produces smaller molecules
- releases useful energy

Anabolic // energy storing (endergonic) synthesis reactions

- requires energy input
- E.g. production of protein or fat
- driven by energy that catabolism releases

Catabolism and Anabolism are inseparably linked

Table 7.6 Amphibolic Pathways of Glucose Metabolism**Anabolic Pathways**

Intermediates from glycolysis are fed into the amino acid synthesis pathway. From there, the compounds are formed into proteins. Amino acids can then contribute nitrogenous groups to nucleotides to form nucleic acids.

Glucose and related simple sugars are made into additional sugars and polymerized to form complex carbohydrates.

The glycolysis product acetyl CoA can be oxidized to form fatty acids, critical components of lipids.

Catabolic Pathways

In addition to the respiration and fermentation pathways already described, bacteria can deaminate amino acids, which leads to the formation of a variety of metabolic intermediates, including pyruvate and acetyl CoA.

Also, fatty acids can be oxidized to form acetyl CoA.

Oxidation-Reduction Reactions

These reactions transfer an electron from one atom to another (or transfer an electron from one molecule to another molecule)

Oxidation

- any chemical reaction in which a molecule **gives up electrons** and releases energy
- molecule is said to be **oxidized** in this process
- electron acceptor molecule is the **oxidizing agent** // oxygen is often involved as the electron acceptor

Reduction

- any chemical reaction in which a **molecule gains electrons** and also gains energy
- molecule is said to be **reduced** when it accepts electrons
- molecule that donates electrons is the **reducing agent**

Oxidation-reduction (redox) reactions

- oxidation of one molecule is always accompanied by the reduction of another
- electrons are often **transferred as hydrogen atoms**
- molecules like NAD and FAD (i.e. co-enzymes) are used to transfer H⁺ and electron

Reducing agent
gives up electrons.

Oxidizing agent
accepts electrons.

Oxidized
cation

Reduced
anion

Sodium is oxidized and
chloride is reduced.

TABLE 2.5

Energy-Transfer Reactions in the Human Body

Exergonic Reactions

Oxidation

Reactions in which there is a net release of energy. The products have less total free energy than the reactants did.

An exergonic reaction in which electrons are removed from a reactant. Electrons may be removed one or two at a time and may be removed in the form of hydrogen atoms (H or H₂). The product is then said to be oxidized.

Decomposition

A reaction such as digestion and cell respiration, in which larger molecules are broken down into smaller ones.

Catabolism

The sum of all decomposition reactions in the body.

Endergonic Reactions

Reduction

Reactions in which there is a net input of energy. The products have more total free energy than the reactants did.

An endergonic reaction in which electrons are donated to a reactant. The product is then said to be reduced.

Synthesis

A reaction such as protein and glycogen synthesis, in which two or more smaller molecules are combined into a larger one.

Anabolism

The sum of all synthesis reactions in the body.

Biochemistry – the study of the arrangement of different elements molecules that compose living organisms

- Carbohydrates
- Fats
- Proteins
- Nucleic acids

Note: See Chapter Two Second Power Point Presentation // Organic and Biochemistry
